Interpreting the Cylinder Envelope Test for Pendular Wave Propagation in the Sediments of the Paracentric Channels of an Active Basin: Application to Sankt-Peterburg. In an active sea bottom, waves are often observed to oscillate in a period of time longer than the natural period of the sediment-water system. On the basis of periodic (cosine) function, the envelope method is applied to evaluate the possible sources of such oscillations, including the refraction in the sand of the free surface of the water layer. Results are presented for the Paracentric channel of the Sankt-Peterburg area.

Abstract The appearance of the female can be considered as a product of sexual selection among males of various species. Due to this, female sexual traits are often sex-limited. Female choice was found to be responsible for the evolution of female pigmentation in several vertebrate taxa. However, there are many examples of sexual dimorphism in the colouration of female colour morphs in populations of the same species. This situation can occur in birds (eg. yolk-sac, altricial), but also in mammalian taxa (eg. the wolf and the dog). Theoretical explanations for such situations include phenotypic plasticity and disruptive selection, but also the differential survival of pigmented and unpigmented individuals. This study explores the role of these factors in explaining differences in female plumage traits between male and female colour morphs of the wolf (*Canis lupus*). We use eight colour features of the head, neck and wings (as used in a previous study) as proxies for a potential variety of sexual selection mechanisms. Further, we develop a matrix that describes the relationship between these colour features in females of each of the colour morphs. Our results demonstrate that differences in the female plumage colouration are mainly driven by disruptive selection. This is consistent with our previous findings in the same population, and in other populations of wolves. The different colour
